EXPERIMENT NO. 1

EXPT 1 : Study of a recent NLP applications: Formulate the problem statement and description for the same.

AIM : Study of a recent NLP application Multilingual Clinical Dialogue System with AI-Driven Lifestyle Assessment Formulating the problem statement and description for the same.

PROBLEM STATEMENT: Doctors often have limited time to collect complete lifestyle information, and language barriers can lead to incomplete patient communication. This results in missed lifestyle-related health risks and delayed preventive care. An AI-powered multilingual clinical dialogue system can automatically assess lifestyle habits, identify potential risks, and support doctors with structured insights for better clinical decision-making.

THEORY: The Multilingual Clinical Dialogue System with AI-Driven Lifestyle Assessment (MCDS) is an intelligent healthcare application that assists doctors by automatically collecting, understanding, and analyzing patient information during clinical consultations. The system combines Artificial Intelligence (AI), Natural Language Processing (NLP), OpenAI Whisper Speech-to-Text (STT), and Large Language Models (LLMs) to facilitate multilingual communication and provide structured clinical insights. The primary objective of the application is to support preventive healthcare by identifying lifestyle-related risk factors that may contribute to chronic diseases such as diabetes, hypertension, obesity, and cardiovascular disorders.

Unlike conventional consultations, where doctors have limited time to gather detailed lifestyle information, the proposed system acts as an AI-powered clinical assistant. The consultation begins when the patient describes symptoms through voice input. OpenAI Whisper converts the patient's speech into accurate text, even when the conversation is in different languages or accents. This multilingual speech recognition capability enables patients to communicate comfortably in their preferred language while ensuring accurate transcription of medical conversations.

After transcription, the system uses Natural Language Processing (NLP) and a Large Language Model (Llama 3) to understand the patient's symptoms and automatically ask relevant follow-up questions related to lifestyle factors such as sleep duration, diet, physical activity, smoking habits, alcohol consumption, stress levels, daily water intake, and sedentary behaviour. The AI extracts important medical and lifestyle information from the conversation and converts unstructured text into structured clinical data.

The collected information is then analyzed to identify potential lifestyle-related health risks. Based on the patient's responses, the system calculates a Lifestyle Wellness Score, detects unhealthy behavioural patterns, and generates personalized health recommendations following preventive healthcare guidelines. Finally, a structured clinical report containing symptoms, lifestyle assessment, identified risk factors, wellness score, and AI-generated recommendations is presented to the doctor, enabling faster and more informed clinical decision-making.

This application is particularly beneficial for telemedicine platforms, multilingual hospitals, rural healthcare centres, and preventive healthcare systems, where language barriers and limited consultation time often affect the quality of patient assessment. By automating lifestyle assessment using OpenAI Whisper for multilingual speech recognition and AI-based language understanding, the system improves communication, enhances clinical documentation, and supports early detection of chronic disease risks.

FUNCTION OF THE APPLICATION

- Accepts patient voice input in multiple languages.
- Uses OpenAI Whisper to convert speech into accurate text.
- Understands patient symptoms using AI and NLP.
- Automatically asks lifestyle-related follow-up questions.
- Collects information on sleep, diet, exercise, stress, smoking, alcohol, water intake, and sedentary habits.
- Analyzes responses to identify lifestyle-related health risks.
- Calculates a Lifestyle Wellness Score.
- Generates personalized preventive healthcare recommendations.
- Produces a structured clinical summary for doctors.
- Supports multilingual communication and improves clinical decision-making.

CONCLUSION: Through this project, I learned how Artificial Intelligence, Natural Language Processing and OpenAI Whisper can be integrated to build an intelligent multilingual healthcare application. I understood the importance of speech-to-text technology in enabling communication across different languages and how AI can analyze patient conversations to extract meaningful clinical and lifestyle information. This project also enhanced my knowledge of preventive healthcare, conversational AI, clinical data processing, and AI-assisted decision support systems. Overall, it helped me understand how modern AI technologies can improve healthcare accessibility, clinical efficiency, and patient outcomes.

EXPERIMENT NO. 1

EXPT 1 : Study of a recent NLP applications: Formulate the problem statement and description for the same.

AIM : Study of a recent NLP application **Multilingual Clinical Dialogue System with AI-Driven Lifestyle Assessment** Formulating the problem statement and description for the same.

1. Problem Statement

Healthcare professionals often have limited consultation time to gather comprehensive lifestyle information from patients. Important factors such as sleep patterns, diet, physical activity, stress levels, smoking, alcohol consumption, and water intake are frequently overlooked or not discussed in detail during routine consultations. As a result, lifestyle-related risk factors associated with chronic diseases may remain unidentified, affecting preventive healthcare and clinical decision-making.

The challenge becomes greater in multilingual healthcare environments, where language differences can hinder effective communication between doctors and patients. Patients may find it difficult to explain their symptoms and lifestyle habits in a language they are not comfortable with, leading to incomplete or inaccurate clinical information. Existing healthcare systems primarily focus on symptom collection and often lack automated multilingual lifestyle assessment during patient interactions.

To address these challenges, a Multilingual Clinical Dialogue System with AI-Driven Lifestyle Assessment is proposed. The system uses OpenAI Whisper to convert multilingual speech into text and employs AI and Natural Language Processing (NLP) to understand patient conversations, automatically collect lifestyle information, identify potential health risks, and generate structured clinical summaries with personalized recommendations. This enables doctors to make faster, more informed decisions while improving preventive healthcare and patient outcomes.

2. Theory

The Multilingual Clinical Dialogue System with Lifestyle Assessment is an AI-based healthcare system designed to enhance doctor–patient consultations by automatically collecting and analysing lifestyle information during clinical conversations. The system interacts with patients by asking questions related to their daily habits, such as sleep, diet, exercise, stress, smoking, and water intake. It then evaluates the responses to identify lifestyle-related health risks, generates a lifestyle wellness score, and provides personalized health recommendations along with a structured clinical summary for the doctor. This approach helps healthcare professionals make faster and more informed clinical decisions, supports preventive healthcare, improves patient awareness, and promotes healthier long-term outcomes by ensuring that important lifestyle factors are considered during diagnosis and treatment**.**

Several AI-based healthcare systems have demonstrated the effectiveness of conversational interfaces, multilingual communication, and clinical decision support in improving healthcare delivery. These systems provide the foundation for the proposed Multilingual Clinical Dialogue System (MCDS) by

addressing challenges related to symptom collection, language accessibility, preventive healthcare, and clinical decision-making.

2.1 Diagnostic Dialogue and Structured History-Taking

The Nature paper introducing AMIE frames the core research problem precisely: diagnostic dialogue is a complex clinical skill requiring history-taking, diagnostic reasoning, management planning and communication evaluation axes that a chatbot-style question list alone does not satisfy. AMIE's self-play simulated-environment training and state-aware reasoning framework represent one answer to "how do you keep a multi-turn clinical conversation on track," which is the same problem MCDS's System Workflow (patient speaks → AI asks targeted lifestyle questions → AI analyses responses) is attempting to solve at a narrower, lifestyle-screening scope rather than full differential diagnosis.

2.2 Multilingual and Low-Resource Clinical NLP

Recent research on multilingual medical language models has shown that domain-specific pre-training significantly improves the performance of clinical Natural Language Processing (NLP) tasks such as patient screening and named entity recognition across multiple languages. The study also demonstrated strong cross-lingual transferability, indicating that a single multilingual model, when adapted with medical knowledge, can effectively support multiple low-resource languages without requiring separate models for each language. This finding aligns with the design philosophy of the proposed Multilingual Clinical Dialogue System (MCDS), which utilizes multilingual language understanding to provide clinically relevant conversations across different languages. Another recent study introduced a multilingual clinical text simplification framework capable of converting complex medical documents, such as discharge summaries and medication instructions, into patient-friendly versions in Hindi, Tamil, and Telugu while preserving medical accuracy. This approach is particularly relevant to MCDS, where clinical explanations, lifestyle recommendations, and treatment guidance must be communicated clearly in the patient's native language. In addition, multilingual medical language models trained on large healthcare datasets have demonstrated their effectiveness in supporting multilingual clinical applications. Overall, these studies highlight significant progress in multilingual medical NLP while also revealing that research on Indian and code-mixed languages remains limited, emphasizing the need for further development of multilingual AI systems for healthcare.

2.3 Lifestyle- and Behaviour-Driven Chronic Disease Risk Prediction

A ScienceDirect study mining electronic health record documentation for lifestyle-modification patterns found that machine learning identified BMI, provider specialty, and family history of alcohol misuse, metabolic disorder and cardiovascular disease as the strongest predictors of whether a lifestyle intervention was documented and explicitly flags that clinical NLP for extracting such signals remains far less developed outside English, the same gap MCDS's multilingual design is intended to close.

A systematic review and meta-analysis in the European Heart Journal — Digital Health assessed machine-learning models for primary-prevention cardiovascular risk built on EHR data, evaluating them against frameworks such as TRIPOD-AI, while a Frontiers in AI study using a bidirectional GRU on EHR-derived embeddings predicted three-year onset of Type 2 diabetes, COPD, hypertension and acute MI with AUROC values between 0.92 and 0.94, using SHAP values to confirm the model had learned clinically recognised risk

factors. Together with an arXiv study predicting chronic-disease hospitalisation from EHR history using SVM, logistic regression and random forests, this literature establishes that structured lifestyle and history variables sleep, diet, activity, smoking, stress, exactly the eight fields MCDS collects — are established, validated predictors of chronic-disease risk, not an invented feature set.

3. Description

To understand the significance of the proposed Multilingual Clinical Dialogue System (MCDS), it is important to examine existing AI-powered healthcare systems and recent research in multilingual clinical Natural Language Processing (NLP). Several government initiatives, healthcare organizations, and research institutions have developed conversational AI systems that assist in symptom collection, clinical decision support, multilingual communication, and preventive healthcare. These existing solutions demonstrate the growing role of AI in improving healthcare delivery and provide a strong foundation for the design and development of MCDS. The following sections review these deployed systems and relevant research to identify current capabilities, limitations, and opportunities addressed by the proposed system.

3.1 eSanjeevani and its AI Clinical Decision Support System

eSanjeevani is India's national telemedicine platform developed by the Ministry of Health and Family Welfare in collaboration with C-DAC. It provides AI-assisted clinical decision support by collecting structured patient symptoms before teleconsultation and suggesting possible diagnoses and appropriate departments to healthcare professionals. The platform supports multiple Indian languages, making remote healthcare services accessible to a diverse population. Its structured symptom collection and multilingual approach closely resemble the workflow followed by the proposed MCDS.

3.2 WHO S.A.R.A.H — Generative AI Digital Health Promoter

The World Health Organization's S.A.R.A.H. (Smart AI Resource Assistant for Health), launched in April 2024, is a generative-AI avatar available 24/7 in eight languages via text or video. It is explicitly framed around lifestyle and preventive counselling helping people understand risk factors for cancer, heart disease, lung disease and diabetes, and giving guidance on quitting tobacco, staying active, eating well and de-stressing — which is precisely the lifestyle-question domain (sleep, diet, exercise, smoking, stress) that MCDS automates during a clinical conversation. A 2025 qualitative case study analysed S.A.R.A.H. against the WHO's own 2021 ethics guidance for AI in health, finding real gaps between stated ethical principles and practice, particularly around adolescent users a caution directly relevant to any lifestyle-assessment AI collecting sensitive personal-habit data.

3.3 Google AMIE — Conversational Diagnostic AI (Research Benchmark)

Google Research's AMIE (Articulate Medical Intelligence Explorer) is the most rigorously evaluated conversational diagnostic AI to date. In a randomized, double-blind, OSCE-style crossover study covering 159 case scenarios from Canada, the UK and India, AMIE outperformed 20 primary-care physicians on 30 of 32 specialist-rated axes and 25 of 26 patient-actor-rated axes, including history-taking and diagnostic accuracy, when interacting over synchronous text chat. AMIE has since been extended to multimodal reasoning (interpreting patient-submitted images mid-conversation) and, most recently, tested in a real-world, IRB-

approved feasibility study with Beth Israel Deaconess Medical Center, where it helped gather pre-visit patient history ahead of primary-care appointments.

AMIE is a research system, not a public deployment, and its authors are explicit that a text-chat interface is unfamiliar in normal clinical practice and that further validation is required before real-world translation. It nonetheless sets the evidentiary bar for what an LLM-driven diagnostic dialogue system can achieve, and is the closest published analogue to MCDS's "patient speaks → AI asks → AI analyses → doctor receives summary" workflow.

3.4 Sector Context: Wearables and Chronic-Disease Digital Programmes

Beyond dialogue-first systems, national and private telemedicine platforms increasingly pair AI intake with chronic-disease management: eSanjeevani's own roadmap cites Azure OpenAI-based work toward multilingual consultations and simplified prescriptions, while private Indian telemedicine platforms differentiate on chatbot- and wearable-integrated user experience. This is the same direction MCDS's stated future roadmap points toward wearable integration, automatic BMI calculation and weekly progress tracking rather than a novel category of feature.

4. Comparative Summary

Table 1. Selected deployed systems and academic studies relevant to multilingual clinical dialogue and lifestyle risk assessment.

System / Study	Core Approach	Reported Result	Language Scope
eSanjeevani AI CDSS (C-DAC, MoHFW)	SNOMED-aligned structured symptom form + AI differential-diagnosis and routing suggestions	Deployed to ~330M+ patients; symptom set expert-validated over 3 rounds	English + 12 regional Indian languages via Bhashini
WHO S.A.R.A.H.	Generative-AI avatar for preventive/lifestyle health counselling (video or text)	24/7 public prototype; ethics gaps flagged in 2025 case study	8 languages
Google AMIE	Self-play-trained LLM optimised for diagnostic dialogue and history-taking	Outperformed PCPs on 30/32 specialist-rated axes (OSCE study, 159 cases)	English (research setting)
Multilingual BERT for medical tasks (2025)	Domain-adapted mBERT for clinical NER and patient screening	Domain pre-training improved task performance; cross-lingual transfer observed	Dutch, Romanian, Spanish
Indic Clinical Text Simplification (ACL 2025)	mT5 + IndicTrans2 pipeline simplifying discharge summaries / medication instructions	Human-rated readability and factual-accuracy scores reported per language	English, Hindi, Tamil, Telugu
EHR lifestyle-modification ML study (ScienceDirect)	Statistical + ML models (logistic regression, decision trees, random forests) on CDW data	BMI, family history of alcohol/metabolic/CV disease were top predictors	English
GRU chronic-disease onset model (Frontiers AI)	Bidirectional GRU over EHR embeddings + SHAP explainability	AUROC 0.92–0.94 for diabetes, COPD, hypertension, MI (3-yr onset)	English

System / Study	Core Approach	Reported Result	Language Scope
LLM-extracted psychosocial features (opioid retention study, 2025)	LLM feature extraction from clinical narrative + SHAP-ranked prediction model	Moderate accuracy gain over structured-data-only baseline	English

5. Where MCDS Sits in This Landscape

Read against this evidence base, MCDS's architectural choices track the direction the field and government deployments are already moving in, rather than inventing a new category:

- Multilingual handling through an LLM's native capability (Llama 3 / GPT, Whisper for speech-to-text) mirrors the government's own move — Bhashini plugged into eSanjeevani — toward treating multilingual understanding as shared or model-native infrastructure rather than a hand-built per-language pipeline.
- Structured lifestyle capture (sleep, exercise, smoking, diet, water intake, stress, sedentary hours) followed by AI risk-factor analysis is the same framing used in eSanjeevani's SNOMED-aligned symptom form and in the EHR-based lifestyle/chronic-disease prediction literature — a validated approach, not a novel one.
- Structured, doctor-facing output (symptom summary, risk factors, wellness score, recommendations) at the point of consultation is the same design goal as eSanjeevani's AI CDSS output shown to the remote physician — MCDS applies it specifically to preventable lifestyle risk rather than differential diagnosis.
- The genuine point of differentiation is scope and integration: MCDS is scoped narrowly and consistently to lifestyle-risk screening embedded directly inside the doctor–patient conversation, rather than being a separate chatbot (S.A.R.A.H.) or a full diagnostic-dialogue agent (AMIE) that a patient must seek out independently.

6. Research Gaps Worth Naming Honestly

- Real-world validation at scale: AMIE's strongest evidence remains a simulated OSCE study and a single-site feasibility trial; none of the systems reviewed here report large-scale, multi-year field validation of AI-generated lifestyle risk assessments against clinical outcomes.
- Indic and code-mixed language coverage: most open multilingual medical NLP work (Medical mT5, mBERT domain-adaptation studies) still concentrates on English and a small set of European languages; Indian-language clinical NLP resources such as the IndicTrans2-based simplification pipeline are recent (2025) and narrow in scope.
- Sensitive-data ethics: the 2025 case study of WHO S.A.R.A.H. found concrete gaps between the WHO's own AI-ethics guidance and practice, particularly for adolescent users — a direct caution for any system, including MCDS, that collects self-reported habits such as smoking, alcohol use, or stress levels.
- Feature reliability from free text: the opioid-retention study shows LLM-extracted psychosocial features improve prediction only moderately over structured data, and depend on how faithfully the LLM converts conversational nuance into discrete risk flags — an open question for MCDS's own AI-analysis stage.
- Evaluation transparency: several of the strongest reported accuracy figures above (0.92–0.94 AUROC, 30/32 axes) come from held-out or simulated evaluation sets; comparability across studies is limited by differing datasets, disease definitions and population characteristics.

7. Conclusion

From this case study, I understood that Artificial Intelligence is becoming an important technology for improving healthcare, especially in doctor–patient communication and preventive healthcare. Many patients do not provide complete information about their lifestyle habits, such as sleep patterns, diet, physical activity, stress levels, smoking, and water intake, because of limited consultation time or communication barriers. These missing details can affect the early detection and prevention of chronic diseases. A multilingual AI-based clinical dialogue system can help overcome this challenge by interacting with patients in their preferred language, collecting structured lifestyle information, analysing potential health risks, and providing meaningful summaries to doctors before or during consultation.

I also learnt that the proposed Multilingual Clinical Dialogue System (MCDS) is not an entirely new concept but a combination of several proven technologies and healthcare approaches. Existing systems such as eSanjeevani, WHO S.A.R.A.H., and Google AMIE demonstrate that conversational AI, multilingual communication, and AI-assisted clinical decision support are already being successfully applied in healthcare. The proposed system brings these capabilities together with a specific focus on lifestyle assessment and preventive healthcare during routine doctor–patient interactions.

Another important learning from this study is that multilingual Natural Language Processing (NLP) has made significant progress, enabling AI systems to understand and communicate in multiple languages. However, there is still limited research and fewer resources available for Indian and code-mixed languages, highlighting the need for further development of multilingual healthcare AI systems that can effectively serve diverse populations.

This case study also helped me understand that AI should be viewed as a decision-support tool rather than a replacement for healthcare professionals. While AI can efficiently collect patient information, identify possible lifestyle-related health risks, and generate recommendations, final diagnosis and treatment decisions must always remain with qualified medical practitioners. AI improves consultation efficiency by assisting doctors with structured information, allowing them to focus more on patient care.

Finally, I learnt that although AI-based healthcare systems show promising results, there are still important challenges that need to be addressed. These include validating AI systems in real-world clinical environments, ensuring patient privacy and ethical use of sensitive health data, improving support for Indian languages, and continuously evaluating the accuracy and reliability of AI-generated recommendations. Overall, this case study demonstrates that integrating multilingual conversational AI with lifestyle assessment has the potential to strengthen preventive healthcare and improve clinical decision-making, provided that such systems are carefully validated and deployed under the supervision of healthcare professionals.
